(54) Method and system for digital beam forming

(57) A digital beam forming system includes an array of computing units (60-76) for weighting incoming signals and a plurality of summing processors (80-84) for generating output signals that represent weighted sums corresponding to rows within the array. The digital beam forming system can be incorporated in either a transmitter or receiver used in a radio frequency communications system.

Related Inventions

5

The present invention is related to the following inventions which are assigned to the same assignee as the present invention:

(1) "Logarithm/Inverse-Logarithm Converter Utilizing Linear Interpolation and Method of Using Same", having Serial No. 08/391,880, filed on February 22, 1995;

(2) "Logarithm/Inverse-Logarithm Converter Utilizing a Truncated Taylor Series and Method of Use Thereof", having Serial No. 08/381,167, filed on January 31, 1995;

(3) "Logarithm/Inverse-Logarithm Converter and Method of Using Same", having Serial No. 08/381,368, filed on January 31, 1995; and

(4) "Logarithm/Inverse-Logarithm Converter Utilizing Second-Order Term and Method of Using Same", having Serial No. 08/382,467, filed on January 31, 1995.

The subject matter of the above-identified related inventions is hereby incorporated by reference into the disclosure of this invention.

Technical Field

30 The present invention relates generally to signal processing in radiated wave communication systems and, in particular, to a beam forming antenna system.

Background of the Invention

The electromagnetic environment is becoming increasingly dense with the proliferation of wireless personal communication devices, such as cellular phones and pagers. Ever more information and sophistication are required from wireless communication systems, placing greater demands on antenna performance. Digital beam forming is a powerful technique for augmenting antenna performance.

The basic principles of digital beam forming have been described in literature. See for example, "Digital Beam forming Antennas An Introduction", by Hans Steyskal, Microwave Journal, January 1987.

Generally, a digital beamformer operates in conjunction with a phase-array antenna to enhance the overall quality of radiated data signals. In a receiver, a radiated wave front impinging on an array antenna causes signals received at various antenna elements to differ in phase due to the angle of the wave front relative to the array. The digital beamformer compensates for this phase shift and sums together the different element signals such that maximum signal-to-noise ratio is obtained at its output. In the transmit direction, the beamformer's operation can be reversed, such that the transmitted signal can be made to travel in any desired direction by applying the appropriate phase shifts to each of the element signals.

Although a variety of techniques for beam forming have been developed, current digital beam forming antenna systems lack the computational performance required by many communication system applications. Consequently, there is a need for a digital beam

forming system that provides high-performance computational power at low cost.

5 **Brief Description of the Drawings.**

The invention is pointed out with particularity in the appended claims. However, other features of the invention will become more apparent and the invention will be best understood by referring to the following detailed description in conjunction with the accompanying drawings in which:

FIG. 1 shows a block diagram of an receiver that incorporates a digital beam forming system.

15 FIG. 2 shows a block diagram of a transmitter that incorporates a digital beam forming system.

FIG. 3 shows a block diagram of a digital beam former that is accordance with an embodiment of the present invention.

20 FIG. 4 shows a block diagram representing a first embodiment of a computing unit usable in the digital beam former of FIG. 3.

FIG. 5 shows a block diagram representing a second embodiment of a computing unit usable in the 25 digital beam former of FIG. 3.

FIG. 6 shows a block diagram representing a third embodiment of a computing unit usable in the digital beam former of FIG. 3.

30 FIG. 7 shows a block diagram representing a first embodiment of a summing processor that is usable in the digital beam former of FIG. 3.

FIG. 8 shows a block diagram representing a second embodiment of a summing processor that is usable in the digital beam former of FIG. 3.

FIG. 9 shows a block diagram of a digital beam former that is in accordance with a second embodiment of the present invention.

5 FIG. 10 illustrates a flow diagram of a method of using the digital beam forming system of FIG. 3 in a receiver.

FIG. 11 illustrates a flow diagram of a method of using the digital beam former of FIG. 3 in a transmitter.

FIG. 13 illustrates a flow diagram of a method of using the digital beam former of FIG. 9 in a transmitter.

15

Detailed Description of a Preferred Embodiment

It is an advantage of the present invention to provide a system for digital beam forming that economically affords the intensive computational performance required by modern digital phased-array antennas. It is also an advantage of the present invention to provide a method and system of beam forming that can adaptively form or null multiple beams.

FIG. 1 shows a block diagram of an array-antenna receiver that incorporates a digital beam former 32 that conforms to an embodiment of the present invention. The receiver includes an array-antenna 20, one or more receiver modules 26, one or more analog-to-digital (A/D) converters 28, the digital beam former 32, and a digital beam steering module 34.

The array-antenna 20 includes elements 22 arranged in a linear array. Received radio frequency (RF) signals are detected and digitized at the element

level. The received signals have generally equal amplitudes, but different phases at each element. The signals can represent any number of communication channels.

5 In response to the received signals, the receiver modules 26 generate analog signals. The receiver modules 26 perform the functions of frequency down-conversion, filtering, and amplification to a power level commensurate with the A/D converter 28. The
10 phase information of the radiated signals is preserved via an in-phase (I) and quadrature (Q) component included in the analog signal. The I and Q components respectively represent real and imaginary parts of the complex analog signal. There is preferably a one-to-one correspondence between the elements 22 and receiver modules 26.

15 The A/D converters 28 sample and digitize the analog signals to produce digital signals. Each A/D converter is dedicated to processing the signals produced by a respective array element. After the A/D conversion, the digital signals go to the digital beamformer 32 which computes weighted sums y_i representing inner-product beams. Typically, an inner-product beam represents a single communication
20 channel.

25 Weight values w_{ij} are passed to the digital beam former 32 by the digital beam steering module 34. Using a suitable algorithm, the digital beam steering module 34 adaptively determines the proper weights.
30 This can be done a relatively slow rate compared to the overall data throughput of the antenna system.

35 FIG. 2 shows a block diagram of an array-antenna transmitter that incorporates a digital beam former 40 that is in accordance with an embodiment of the present invention. The transmitter includes the

digital beam former 40, a digital beam steering module 42, one or more digital-to-analog (D/A) converters 44, one or more transmitter modules 46, and the array-antenna 20.

5 Incoming signals representing one or more channels are passed to the digital beam former 40 and the digital beam steering module 42. The incoming signals include phase information (I and Q components) for each channel. The digital beam former outputs
10 weighted sums corresponding to the elements 22 of the array-antenna 20.

The weights w_{ij} are passed to the digital beam former 40 by the digital beam steering module 42. Using a suitable algorithm, the digital beam steering
15 module 42 adaptively determines the proper weights.

The D/A converters 44 convert the digital output signals of the beam former 40 into corresponding analog signals. The transmitter modules 46 generate radiatable signals in response to the analog signals.
20 The transmitter modules 46 perform the functions of frequency up-conversion, filtering, and amplification. The radiatable signals are then transmitted through the elements 22 of the array-antenna 20.

The digital beam forming antenna systems shown in FIGS. 1-2 have advantage over conventional fixed beam antennas because they can separate closely spaced beam, adaptively adjust beam patterns in response to incoming data, and improve pattern nulling of unwanted RF signals.

30 FIG. 3 shows a block diagram of the digital beam former according to an embodiment of the present invention. The beam former includes a plurality of computing units (CU's) 60-76 and a plurality of summing processors 80-84. The computing units 60-76 form a processor array. Each column in the processor
35

array receives a corresponding digital signal x_i . Upon receiving a digital signal, each computing unit independently weights the signal to generate a weighted signal. The summing processors 80-84 provide 5 a means for summing weighted signals generated by a respective row to produce outputs y_i . Essentially, each output signal represents a weighted sum having a form:

$$y_i = \sum_{j=1}^n w_{ij} x_j \quad \text{where } i = 1, 2, \dots, m.$$

(1)

15 Equation (1) can be construed as representing the general form of a discrete Fourier transform. Consequently, the architecture of the digital beam former lends itself to high-speed, parallel computation of discrete Fourier transforms.

20 FIG. 4 shows a block diagram representing a first embodiment of a computing unit usable in the digital beam former of FIG. 3. The computing unit includes a multiplier 90 and a memory circuit 92. The computing unit weights an incoming digital signal by multiplying it by a pre-computed weight value w_{ij} stored in the 25 memory circuit 92. The output of the multiplier 90 represents the weighted signal.

The memory circuit 92 can be any means for storing values whose contents is updatable by the 30 digital beam steering module 34, 42, such as a ROM (read only memory), EEPROM (electrically erasable programmable read only memory), DRAM (dynamic random access memory), or SRAM (static random access memory).

35 FIG. 5 shows a block diagram representing a second embodiment of a computing unit usable in the

digital beam former of FIG. 3. In this embodiment of the computing unit, an incoming signal is weighted using logarithmic number system (LNS) arithmetic. LNS-based arithmetic provides advantage because 5 multiplication operations can be accomplished with adders instead of multipliers. Digital adder circuits tend to be much smaller than comparable multiplier circuits, thus, the size the beam forming processor array can be reduced by incorporating LNS-based 10 computing units.

The LNS-based computing unit includes a log converter 100, an adder 102, a memory circuit 104, and an inverse-log (\log^{-1}) converter 106. An incoming signal is first converted to its respective log signal 15 by the log converter 100. The adder 102 then sums the log signal and a logged weight value from the memory circuit 104 to produce a sum. The sum is then converted to the weighted signal by the inverse-log converter 106.

20 The log converter 100 and inverse-log converter 106 can be implemented using any of the converters described in the co-pending U.S. patent applications of above-identified Related Inventions Nos. 1-4.

FIG. 6 shows a block diagram representing a third 25 embodiment of a computing unit usable in the digital beam former of FIG. 3. This embodiment of the computing unit is intended to weight complex signals. In many applications, the I and Q components of the complex digital signals are represented by a pair of 30 3-bit words. Although it is not limited to small word lengths, the computing unit of FIG. 6 provides advantage in such applications because it requires less power and space when implemented using an integrated circuit.

The computing unit includes a first switch 110, a first memory circuit 112, a second switch 114, a second memory circuit 116, a subtractor 118, and an adder 120. The first memory 112 stores first pre-computed values that are based on an imaginary weight W_i . The second memory 116 stores second pre-computed values that are based on a real weight W_r .

5 The purpose of the computing unit is to multiply two complex numbers:

$$10 (I + iQ)(W_r + iW_i) = (IW_r - QW_i) + i(IW_i + QW_r)$$

(2) Essentially, the computing unit calculates the right-hand side of equation (2). The first memory 112 stores the pre-computed values IW_i and QW_i , while the second memory 116 stores the pre-computed values IW_r and QW_r . It will be apparent to one of ordinary skill in the art that using 3-bit words to represent the 15 complex components and weights would require each memory to store eight 6-bit words.

20 The first switch 110 provides a means for addressing the first memory circuit using either the I or Q component to select one of the first pre-computed values as the first memory circuit output. The second switch 114 provides a means for addressing the second memory 116 using either the I or Q component to select one of the second pre-computed values as the second memory circuit output.

25 The subtractor 118 subtracts the first memory output from the second memory output to generate the weighted in-phase component $(IW_r - QW_i)$ that is then included in the weighted signal. The adder 120 sums the first memory output and the second memory output

to generate the weighted quadrature component ($IW_i + QW_r$) that is also included in the weighted signal.

In one embodiment of the computing unit, the subtractor 118 includes an adder capable of summing 5 2s-complement numbers. The pre-computed values are either stored in the memory as 2s-complement values or additional logic circuitry is placed in the computing unit to convert the pre-computed values to their respective 2s-complement values.

10 Preferably, the subtractor 118 includes an adder having a carry input set to one and inverters to form the 1s-complement value of the second memory output. The adder effectively utilizes the 2s-complement value 15 of the second memory output by summing the carry input and the 1s-complement value.

FIG. 7 shows a block diagram representing a first embodiment of a summing processor that is usable in the digital beam former of FIG. 3. This particular embodiment of the comprises an adder tree 130. The 20 adder tree 130 includes adders which are connected together in a fashion which allows three or more input signals to be summed concurrently. When using the adder tree topology depicted by FIG. 7, $N-1$ adders are required to sum N inputs. Regarding the example shown 25 in FIG. 7, eight input signals can be received simultaneously, thus, seven adders are required in the adder tree 130. If one wishes to sum a greater number of input signals, more adders are required. For instance, in order to sum 128 input signals, the adder 30 tree would require 127 adders. The adder tree 130 has advantage because it presents less of a delay in providing output sums.

FIG. 8 shows a block diagram representing a second embodiment of a summing processor that is 35 usable in the digital beam former of FIG. 3. This

summing processor embodiment includes a plurality of summers 140-148, a plurality of delay circuits 150-154, and a ripple adder 156. Although this summing processor topology may require more time to generate a final sum than a comparable adder tree, it requires less area when implemented in an integrated circuit.

Each of the summers 140-148 sums weighted signals from a group of computing units residing in a same row to produce a weighted sum signal. A summer can include any means for summing weighted signals, such as an adder tree or an accumulator that sequentially adds inputs.

The delay circuits 150-154 produce delayed signals by buffering the weighted sum signals for a predetermined time. Generally, the weighted signals are produced at the summer outputs at approximately the same time. In order to correctly sum the weighted signals, it is necessary to delay weighted signals that are generated in the downstream portion of a processor row. The delay time is a function of the location of the group of computing units within the processor columns.

The ripple adder 156 includes two or more adders 158-164 cascaded together in order to sum the delayed signals and first two weighted sums. The output of the ripple adder 156 represents the total sum of all weighted signals in a given processor row.

FIG. 9 shows a block diagram of a digital beam former that is in accordance with a second embodiment of the present invention. This embodiment of the beam former includes a log converter 170, a plurality of computing units 172-188, an inverse-log converter 190, and a plurality of summing processors 192-196. The computing units 172-188 form a processor array. Incoming digital signals are first converted to log

signals by the log converter 170. Each column in the processor array receives a corresponding log signal. Upon receiving a log signal, each computing unit independently weights the signal to generate a sum signal. The sum signals are then converted to weighted signals by the inverse-log converter 190. For each processor row, the weighted signals are respectively summed by one of the summing processors 192-196 to generate an output signal.

The log converter 170 and inverse-log converter 190 can be implemented using any of the converters described in the co-pending U.S. patent applications of above-identified Related Inventions Nos. 1-4.

FIG. 10 illustrates a flow diagram of a method of using the digital beam former of FIG. 3 in a receiver.

In box 200, incoming radiated signals are down-converted into analog signals. In box 202, the analog signals are sampled and digitized into digital signals. In box 204, the digital signals are distributed to the array of computing units. Next, in box 206, the digital signals are weighted to generate the weighted signals. In box 208, the weighted signals are respectively summed for each of the processor rows, whereby producing the output signals.

Regarding box 206, the digital signals can be weighted as a function of one or more pre-computed values that are retrieved from a memory circuit. This can be accomplished by multiplying the digital signals by the weight values. The stored values are pre-computed from the digital signal and can be updated at various times to adaptively alter the weighting of the digital signals.

FIG. 11 illustrates a flow diagram of a method of using the digital beam former of FIG. 3 in a transmitter. This method incorporates the steps

described in conjunction with boxes 204-208 of FIG. 10.

In box 210, the digital output signals of the beam former are converted into analog signals. In box 5 212, the analog signals are up-converted into radiatable signals which can be transmitted through an array-antenna.

FIG. 12 illustrates a flow diagram of a method of using the digital beam former of FIG. 9 in a receiver.

10 This method incorporates the steps described in conjunction with boxes 200-204 of FIG. 10.

In box 220, the digital signals are converted into log signals. In box 222, the log signals are distributed to the array of computing units. Next, in 15 box 224, the log signals are summed with corresponding log-converted weight values to generate the sum signals. In box 226, an inverse-log conversion is performed on the sum signals to produce the weighted signals. In box 228, the weighted signals are 20 respectively summed according to processor rows in order to generate the output signals.

FIG. 13 illustrates a flow diagram of a method of using the digital beamformer of FIG. 9 in a transmitter. This method incorporates the steps 25 described in conjunction with boxes 220-228 of FIG.

12. In box 230, the digital output signals of the beam former are converted into analog signals. In box 232, the analog signals are up-converted into 30 radiatable signals which can be transmitted through an array-antenna.

To summarize, there has been described herein a concept, as well as several embodiments, including a preferred embodiment, of a method and system of 35 digital beam forming which can be used to improve the

performance of array-antenna systems. Because various embodiments of the methods and systems as herein-described utilize arrays of computing units, they can perform massively parallel operations which 5 allows for a vast increase in system performance. Other embodiments of the present invention utilize LNS-based arithmetic which allows the overall size of the computing unit array to be reduced when implemented using digital logic circuits.

10 While specific embodiments of the present invention have been shown and described, it will be apparent to those skilled in the art that the disclosed invention may be modified in numerous ways and may assume many embodiments other than the 15 preferred form specifically set out and described above.

Accordingly, it is intended by the appended claims to cover all modifications of the invention which fall within the true spirit and scope of the 20 invention.

What is claimed is:

1. A method for performing a computation using an array of computing units, the array having a plurality of columns and a plurality of rows, the method comprising:
a) receiving a first input signal and a second input signal; and
b) performing a computation using the array of computing units, the computation being based on the first input signal and the second input signal, the computation resulting in a third output signal.

CLAIMS

1. A processor for beam forming a plurality of channels in a communications system, the processor being operatively coupled to an array-antenna and responsive to a plurality of channel signals, comprising:
 - a plurality of computing units forming an array having a plurality of rows and a plurality of columns,
 - each of the columns weighting one of the channel signals to generate a plurality of weighted signals; and
 - summing means for generating a plurality of output signals in response to the weighted signals.
15. 2. The processor of claim 1, wherein the summing means comprises:
 - a plurality of summers for generating a plurality of weighted sum signals, each of the summers summing ones of the weighted signals corresponding to a group of computing units in a same row to produce one of the weighted sum signals;
 - a plurality of delay circuits for producing a plurality of delayed signals, each of the delay circuits buffering one of the weighted sum signals for a predetermined time that is a function of the plurality of columns; and
 - a plurality of ripple adders, each of the ripple adders summing ones of the delayed signals from a corresponding row to generate one of the output signals.

3. A processor for beam forming a plurality of channels in a communications system, the processor being operatively coupled to an array-antenna and responsive to a plurality of channel signals,

5 comprising:

log means for converting the plurality of channel signals into a plurality of log signals;

10 a plurality of computing units, forming an array having a plurality of rows and a plurality of columns, for generating a plurality of sum signals in response to the log signals; and

summing means for generating a plurality of output signals based on the sum signals.

15 4. The processor of claim 3, further comprising:

inverse-log means for generating a plurality of weighted signals in response to the sum signals.

20 5. The processor according to claims 1 or 3, wherein at least one of the computing units comprises: a memory circuit for storing a plurality of pre-computed weight values; and means for retrieving from the memory circuit at least one pre-computed value in response to the 25 channel signals.

30 6. The processor according to claims 1 or 3, wherein the summing means comprises: a plurality of adder trees for generating the plurality of output signals, each of the adder trees generating one of the output signals as a function of outputs from one of the rows of computing units.

7. The processor according to claims 1 or 3,
for use in a receiver, further comprising:
a plurality of receiver modules, operatively
coupled to a corresponding plurality of elements
5 included in the array-antenna, for down-converting a
plurality of radiated signals into a plurality of
analog signals; and
a plurality of analog-to-digital converters for
sampling and digitizing the plurality of analog
10 signals to produce the plurality of channel signals.

8. The processor according to claims 1 or 3,
for use in a transmitter, further comprising:
a plurality of digital-to-analog converters for
15 generating a plurality of analog signals, each of the
digital-to-analog converters converting one of the
output signals into one of the analog signals; and
a plurality of transmitter modules corresponding
to the digital-to-analog converters for up-converting
20 the analog signals into a plurality of radiatable
signals that are transmittable through a plurality of
elements included in the array-antenna.

9. A method of beam forming a plurality of
25 channels in a communications system, comprising the
steps of:
distributing a plurality of channel signals to a
plurality of computing units forming an array having a
plurality of rows and a plurality of columns;
30 weighting the channel signals to generate a
plurality of weighted signals; and
generating a plurality of output signals, each of
the output signals being generated by summing the
weighted signals corresponding to a respective one of
35 the rows.

10. The method of claim 9, wherein the step of weighting includes the following sub-steps:

- converting the plurality of channel signals into a plurality of log signals;
- 5 summing the plurality of log signals and a plurality of log-converted weight values to generate a plurality of sum signals; and
- 10 performing an inverse-log conversion on the plurality of sum signals to produce the plurality of weighted signals.
